A clinicoepidemiological study of polymorphic light eruption
Lata Sharma, A. Basnet ................................................................................................................................................ 15

A clinico-epidemiological study of PLE was done for a period of one year to include 220 cases of PLE of skin type between IV and VI. The manifestation of PLE was most common in housewives on sun exposed areas. Most of the patients of PLE presented with mild symptoms and rash around neck, lower forearms and arms which was aggravated on exposure to sunlight. PLE was more prevalent in the months of March and September and the disease was recurrent in 31.36% of cases.

Comparative study of efficacy and safety of hydroxychloroquine and chloroquine in polymorphic light eruption: A randomized, double-blind, multicentric study
Anil Pareek, Uday Khopkar, S. Sacchidanand, Nitin Chandurkar, Geeta S. Naik ................................................... 18

In a double-blind randomized, comparative multicentric study evaluating efficacy of antimalarials in polymorphic light eruption, a total of 117 patients of PLE were randomized to receive hydroxychloroquine and chloroquine tablets for a period of 2 months (initial twice daily dose was reduced to once daily after 1 month). A significant reduction in severity scores for burning, itching, and erythema was observed in patients treated with hydroxychloroquine as compared to chloroquine. Hydroxychloroquine was found to be a safe antimalarial in the dosage studied with lesser risk of ocular toxicity.
Many faces of cutaneous leishmaniasis
Arfan Ul Bari, Simeen Ber Rahman

Symptomatic cutaneous leishmaniasis is diverse in its presentation and outcome in a tropical country like Pakistan where the disease is endemic. The study describes the clinical profile and atypical presentations in 41 cases among 718 patients of cutaneous leishmaniasis. Extremity was the most common site of involvement and lupoid cutaneous leishmaniasis was the most common atypical form observed. Authors suggest that clustering of atypical cases in a geographically restricted region could possibly be due to emergence of a new parasite strain.

Forehead plaque: A cutaneous marker of CNS involvement in tuberous sclerosis
G. Raghu Rama Rao, P. V. Krishna Rao, K. V. T. Gopal, Y. Hari Kishan Kumar, B. V. Ramachandra

In a retrospective study of 15 patients of tuberous sclerosis, eight patients had central nervous system involvement. Among these 8 cases, 7 cases had forehead plaque. This small study suggests that presence of forehead plaque is significantly associated with CNS involvement.

INSTRUCTIONS FOR AUTHORS

The copies of the journal to members of the association are sent by ordinary post. The editorial board, association or publisher will not be responsible for non-receipt of copies. If any of the members wish to receive the copies by registered post or courier, kindly contact the journal’s/publisher’s office. If a copy returns due to incomplete, incorrect or changed address of a member on two consecutive occasions, the names of such members will be deleted from the mailing list of the journal. Providing complete, correct and up-to-date address is the responsibility of the members. Copies are sent to subscribers and members directly from the publisher’s address; it is illegal to acquire copies from any other source. If a copy is received for personal use as a member of the association/society, one cannot resale or give-away the copy for commercial or library use.
Extragenital lichen sclerosus of childhood presenting as erythematous patches

Sir,

Lichen sclerosus (LS) originally described by Hallopeau in 1887, is a chronic inflammatory dermatosis of obscure etiology. It is rather a rare mucocutaneous disorder that predominantly affects the genitoanl area with white porcelain-like sclerotic lesions.[1] Its incidence peaks in early childhood and after menopause.[2] Lichen sclerosus occurs in childhood with genital and/or extragenital involvement.

A nine-year-old Caucasian Greek girl presented to our department with asymptomatic ill-defined erythematous lesions of the trunk and thighs. On clinical examination we observed multiple confluent red patches, approximately 1-2 cm in diameter, which had appeared two weeks previously. The genital organs and the oral cavity were without lesions. No lymph nodes were palpable. Her physical examination was otherwise normal. The patient was not on any medication. Her medical and family history was negative for skin diseases. A punch biopsy from a trunk lesion was performed. The histopathological findings were not diagnostic showing hyperkeratosis, dilated capillaries and moderate perivascular lymphocytic inflammatory infiltrate. The patient was treated with a potent topical corticosteroid for three weeks with no significant improvement.

At five months after onset, some of the lesions became hypopigmented sclerotic plaques while others remained erythematous. There were areas where sclerotic and erythematous lesions coexisted [Figure 1]. Mucous membranes remained unaffected. A second punch biopsy from the lumbar region was performed. The histopathological findings of the second punch biopsy showed an epidermis with compact hyperkeratotic scale [Figure 2]. A cleft-like space separated the epidermis from the pale dermis. Atrophy, hyalinization and homogenization of the dermal collagen and a mild band-like lymphohistiocytic infiltration were also observed. Dilated capillaries were noted. These findings were consistent with lichen sclerosus. Furthermore, polymerase chain reaction (PCR) for *Borrelia*-specific DNA in lesional skin was negative. Antinuclear antibodies were also negative. Finally, all routine blood panels were within normal limits.

A potent topical corticosteroid cream was prescribed for 4 weeks. At the 4 week follow-up visit, both erythematous patches and sclerotic plaques remained unchanged. The topical corticosteroid therapy was discontinued and topical pimecrolimus was instituted, twice daily for 6 months. 1 month after initiating treatment with pimecrolimus, skin lesions showed significant regression of both the erythematous and sclerotic component. The patient was assessed at monthly intervals for 12 months and her clinical improvement was sustained during this period. No side-
effects were reported. Moreover, no recurrence occurred during the follow-up period.

Lichen sclerosus is uncommon in childhood. An estimated prevalence of at least 1 in 900 was reported. It is most often seen in the anogenital area. Extragential involvement is even less common. Female to male ratio is 10:1 and it appears more frequently in patients with atopy. In children the onset of symptoms occurs between two to five years of age, although the disease can manifest itself anytime between the ages one to 13 years. Cutaneous LS may exist alone or in association with genital LS in 15-20% of the cases. It can affect any skin site. Lesions consist of asymptomatic white polygonal papules or macules that may coalesce into patches with comedo-like plugs. To our knowledge, this is the first case of extragenital LS of childhood that has initially presented with erythematous skin lesions. The etiology of LS remains unclear. A genetic basis has been suggested, in particular an association with Class I HLA antigens and also with HLA-A29, B44. Other studies have shown an association with human papilloma virus (HPV) or with spirochete, Borrelia. Autoimmune phenomena, hormonal factors and trauma have been implicated in the etiology of the disease. Although considered by some to be localized scleroderma, most agree that LS is a separate entity. However, these two conditions may coexist.

Currently, there is no generally effective treatment available for LS. Most patients are initially treated with potent topical corticosteroids. Various treatments including PUVA, long-wave UVA, topical testosterone and estrogen, topical tacrolimus or pimecrolimus, antimalarial agents, penicillin, topical retinoids and vitamins, have been tried. Our patient responded well to topical pimecrolimus. This is consistent with other reports in the literature. Topical calcineurin inhibitors may represent a safe and effective therapeutic alternative for LS in childhood. Our case is interesting because it is the first report of extragenital LS of childhood that has initially presented with erythematous skin lesions. It is noteworthy that the early lesions of morphea, a condition related to LS, are also erythematous. In addition, we reported five cases of erythematous lesions of nonspecific balanitis in adults that evolved into typical LS of the genitals during the three-year follow up. It can be speculated that an erythematous variant or an early erythematous stage of LS may exist. In conclusion, chronic recalcitrant erythematous skin lesions may herald the onset of LS. Long-term monitoring of such cases is warranted.
