A clinicoepidemiological study of polymorphic light eruption
Lata Sharma, A. Basnet

A clinico-epidemiological study of PLE was done for a period of one year to include 220 cases of PLE of skin type between IV and VI. The manifestation of PLE was most common in housewives on sun exposed areas. Most of the patients of PLE presented with mild symptoms and rash around neck, lower forearms and arms which was aggravated on exposure to sunlight. PLE was more prevalent in the months of March and September and the disease was recurrent in 31.36% of cases.

Comparative study of efficacy and safety of hydroxychloroquine and chloroquine in polymorphic light eruption: A randomized, double-blind, multicentric study
Anil Pareek, Uday Khopkar, S. Sacchidanand, Nitin Chandurkar, Geeta S. Naik

In a double-blind randomized, comparative multicentric study evaluating efficacy of antimalarials in polymorphic light eruption, a total of 117 patients of PLE were randomized to receive hydroxychloroquine and chloroquine tablets for a period of 2 months (initial twice daily dose was reduced to once daily after 1 month). A significant reduction in severity scores for burning, itching, and erythema was observed in patients treated with hydroxychloroquine as compared to chloroquine. Hydroxychloroquine was found to be a safe antimalarial in the dosage studied with lesser risk of ocular toxicity.
Many faces of cutaneous leishmaniasis
Arfan Ul Bari, Simeen Ber Rahman

Symptomatic cutaneous leishmaniasis is diverse in its presentation and outcome in a tropical country like Pakistan where the disease is endemic. The study describes the clinical profile and atypical presentations in 41 cases among 718 patients of cutaneous leishmaniasis. Extremity was the most common site of involvement and lupoid cutaneous leishmaniasis was the most common atypical form observed. Authors suggest that clustering of atypical cases in a geographically restricted region could possibly be due to emergence of a new parasite strain.

Forehead plaque: A cutaneous marker of CNS involvement in tuberous sclerosis
G. Raghu Rama Rao, P. V. Krishna Rao, K. V. T. Gopal, Y. Hari Kishan Kumar, B. V. Ramachandra

In a retrospective study of 15 patients of tuberous sclerosis, eight patients had central nervous system involvement. Among these 8 cases, 7 cases had forehead plaque. This small study suggests that presence of forehead plaque is significantly associated with CNS involvement.

INSTRUCTIONS FOR AUTHORS

The copies of the journal to members of the association are sent by ordinary post. The editorial board, association or publisher will not be responsible for non-receipt of copies. If any of the members wish to receive the copies by registered post or courier, kindly contact the journal’s / publisher’s office. If a copy returns due to incomplete, incorrect or changed address of a member on two consecutive occasions, the names of such members will be deleted from the mailing list of the journal. Providing complete, correct and up-to-date address is the responsibility of the members. Copies are sent to subscribers and members directly from the publisher’s address; it is illegal to acquire copies from any other source. If a copy is received for personal use as a member of the association/society, one cannot resale or give-away the copy for commercial or library use.
Bullous pyoderma gangrenosum associated with ulcerative colitis

Sir,

Pyoderma gangrenosum (PG) is a rare non-infectious neutrophilic dermatosis associated with underlying systemic disease, characterized by distinctive cutaneous ulcers with undermined borders; lesions usually require aggressive therapy and they heal with a characteristic cribriform scar. We report a case of bullous PG associated with ulcerative colitis.

A 55-year-old woman presented with multiple fluid-filled lesions and ulcers over the upper and lower limbs and trunk of two months duration. There was a history of fever and loose stools on and off and loss of weight since two years. History of development of lesions at the site of trauma was elicited. There was no history of extramarital sexual contact, joint pains, mucosal ulcers and any other systemic symptoms. Examination revealed multiple, tender ulcers of varying size with undermined violaceous borders, vesicles and bullae [Figure 1] distributed over bilateral lower and upper limbs, palms and soles and a few over the trunk. Mucosa, hair and nails were normal. Systemic examination revealed no abnormality.

On investigation, peripheral smear showed hypochromic anemia with neutrophilia; renal function tests and liver function tests were within normal limits, serologic testing revealed negativity for VDRL, HIV 1 and -2, ANA, HBsAg and RA factor. Both bacterial and fungal cultures from the surface of ulcer were sterile; chest X-ray and ultrasound abdomen did not reveal any significant abnormality. No reaction was observed with Mantoux test. Colonoscopy and sigmoidoscopy showed red colonic mucosa with multiple ulcers of varying sizes and shapes and few pseudopolyps distributed throughout the length of the colon [Figure 2].
Neutrophilic abscess [Figure 3]. Pyoderma gangrenosum commonly occurs in immunosuppressed patients secondary to accompanying disease, infections or therapy. The pathophysiology is poorly understood, an immune-mediated pathogenesis is suspected, both humoral and cell-mediated abnormalities have been associated with PG.

The skin lesions of PG appear as tender vesiculobullous, papulopustular lesions that develop into painful ulcers with dusky purple borders that are raised and undermined. The base of the ulcer typically reveals both granulation tissue and necrotic material. Lesion may be solitary or multiple and shows pathergy phenomenon. Several variants of PG have been described; ulcerative, pustular, bullous and vegetative, vulvar and peristomal PG. The peristomal PG is a recently recognized variant that occurs primarily in patients with inflammatory bowel disease. The skin lesions usually appear during the course of active bowel disease and frequently concur with exacerbation of colitis.

Other diseases commonly associated with PG include arthritis, hematological diseases and rarely chronic active hepatitis, myeloma, Takayasu’s arteritis, systemic lupus erythematosus, Wegener’s granulomatosis, diabetes mellitus, HIV infection and other neutrophilic pustular dermatoses, particularly Behçet’s syndrome. Several studies have documented patients with PG and Behçet’s syndrome, the two diseases share certain features such as arthritis, pustulation, aphthous lesions of mucous membranes and the phenomenon of pathergy.

The association of PG with ulcerative colitis varies from 1-50% in various studies, however, PG is an extremely rare disease occurring in less than 1% of patients with inflammatory bowel disease with an equal ratio of patients with Crohn’s disease and ulcerative colitis, and similarly various other studies also demonstrated an incidence of less than 1%. Conversely 0.5-5% patients with ulcerative colitis have PG.

Sporotrichoid pattern of malignant melanoma

Sir,
Malignant melanoma is a highly invasive neoplasm of skin, strongly influenced by environmental factors that develop in a genetically susceptible host. Incidence of melanoma is rising in Caucasians although it is a rare presentation in India.[1]

A 28-year-old female presented with multiple painful lesions over her right leg of eight months duration. She was a farmer and claimed that the lesions started as a single painful nodule on the heel following a thorn prick. She ignored it then and subsequently the size and number of the lesions increased to involve the whole right lower limb as linearly arranged nodules. Cutaneous examination revealed multiple tender nodulo-ulcerative lesions with discharge, arranged in linear fashion from heel to thigh, present over the right leg [Figure 1]. Other findings included edema of the feet, thickened lymphatic channels between nodules along with bilateral stony hard, tender inguinal lymph nodes. The patient was previously diagnosed as sporotrichosis and treated with antifungal (itraconazole) drugs for six months in another healthcare facility without any clinical response. A differential diagnosis of sporotrichosis and malignant melanoma was considered. Limb X-ray, KOH smear, gram stained smear and fungal culture were negative. Skin biopsy revealed atypical melanocytes in the epidermis and dermis in nests. General examination revealed multiple generalized lymphadenopathy (axillary, cervical and submandibular lymph nodes). Abdominal sonography showed liver metastasis. Chest X-ray was normal. A diagnosis of malignant melanoma was established and the patient was referred to the oncology department for further management.

The incidence of melanoma continues to rise at an epidemic rate as evidenced by a 101.5% increase from the 1970s to the 1990s.[2,3] Melanoma represents the fifth most common type of cancer, the most common type in women 25-29 years of age and the most common type in Caucasian men 25-44 years of age. But it is rare in Indian patients. Nodular melanoma and melanoma d'emblee are rare types of primary cutaneous malignant melanoma that are invasive and lack intraepidermal component.[4] These lesions when first noted clinically are always palpable, convex in shape, of varying shades, rapidly increasing in size; neglected tumors may be several centimeters in diameter. Ulceration occurs fairly early. They can occur in any portion of the skin/mucosa.[4]

Our patient presented with history of trauma with multiple nodular ulcerative lesions arranged in a linear fashion along the lymphatics over the lower limb which clinically simulated lymphocutaneous sporotrichosis. However, histopathology helped us to reach the correct diagnosis.
