2. Department of Hematology, Ministry of Health Okmeydani Training and Research Hospital, Istanbul

**Abstract**

**Background:** Febrile neutropenia (FN) is generally a complication of cancer chemotherapy in patients with hematological malignancies.

**Objective:** To evaluate the febrile neutropenia episodes of hematological patients and their outcomes with respect to fungal pathogens, primary antifungal prophylaxis antifungal therapy.

**Methods:** All consecutive patients older than 14 years of age and who developed febrile neutropenia episodes from September 2010 to November 2011 were incorporated into this study.

**Results:** In total, we retrospectively evaluated 86 consecutive patients and their 148 neutropenic episodes. Of the 86 patients, 45 were male and the mean age was 47.65±15.06 years (range: 17–82 years). The mean MASCC score was 18.72 ± 9.43. Systemic antifungal drug was initiated to 17 patients with probable fungal infection and 12 patients with possible fungal infection. Of seven patients who received posaconazole prophylaxis, five were treated with systemic fungal infection due to possible fungal infection.

**Conclusions:** It is obvious that more studies focused on primary prophylaxis are needed and primary or secondary antifungal prophylaxis should be evaluated in terms of provided benefits and disadvantages. Timely and appropriately initiated antifungal treatment is one of the most important factors for a good prognosis for recovery from a neutropenic phase.

**Key words:** Hematological patients, febrile neutropenia, antifungal prophylaxis, antifungal treatment

**Introduction**

Febrile neutropenia (FN) is generally a complication of cancer chemotherapy¹. Mortality related with FN has steadily decreased with guidelines, new laboratory tests and serial computed tomography (CT) scanning, with overall mortality rates ranging from as low as 5% in patients with solid tumors (1% in low-risk patients) and as high as 11% in some hematological malignancies². Multinational Association of Supportive Care in Cancer (MASCC) prognostic index indicates that mortality is as low as 3% if the MASCC score is >21, but as high as 36% if the MASCC score is <15³. Invasive fungal infections associated with aspergillosis, disseminated candidiasis, Fusarium, Zygomycetes, etc., are diminished among patients who have prolonged neutropenia and higher MASCC scores, and/or persistent or prolonged fever after 3-7 days of appropriate treatment². Additionally, patients who have acute myeloid leukemia during remission induction chemotherapy and undergo allogeneic hematopoietic stem cell transplantation with prior conditioning chemotherapy are at risk of invasive aspergillosis due to prolonged and profound neutropenia². Empirical antifungal therapy is recommended for presenting persistent neutropenic fever despite 4–7 days of empirical antibiotic therapy¹. However, invasive fungal infection was demonstrated among only 4% of patients who comprised 22%–34% of the
neutropenic patients who had cancer and received an antifungal drug according to established criteria. CT scanning and galactomannan, with a reported sensitivity rate of 58%-65% and specificity of 65%-95% are recommended for preemptive antifungal therapy. Here, we retrospectively evaluated the febrile neutropenia episodes of hematological patients and their outcomes with respect to fungal pathogens, primary antifungal prophylaxis antifungal therapy.

**Methods**

All consecutive patients between September 2010 and November 2011, who were older than 14 years of age and who developed febrile neutropenia episodes during chemotherapy due to hematological cancers in the hematology department at the Ministry of Health, Okmeydaný Training and Research Hospital, Istanbul, Turkey were included in the study. The hematology department is equipped with 23 beds. Patients rooms were designed as single, double and four-person without HEPA filters. Febrile neutropenia (FN) was defined as an oral temperature $>38.5^\circ C$ or two consecutive readings of $>38.0^\circ C$ for 2 h and an absolute neutrophil count $<0.5 \times 10^9/L$, or expected count to fall below $0.5 \times 10^9/L$.

Collected data included patient demographics and diagnosis, episode data, clinical presentation and laboratory findings, clinical therapy, microbiological data and outcome. The febrile neutropenia treatment protocol was based on clinical practice guidelines for the use of antimicrobial agents in neutropenic patients with cancer: from 2002 and the update in 2010 by the Infectious Diseases Society of America.

Empirical antifungal treatment was considered for patients with persistent or recurrent fever after 4–7 days of antibiotics and whose overall duration of neutropenia was expected to be more than 7 days. If CT showed changes associated with fungal infection, amphotericin B (conventional or liposomal, AM-B) or voriconazole (VOR) were initiated. Cavitation, air-crescent sign and halo sign were classified as the major changes. Nodules and new infiltrates, including consolidation and effusions, were classified as minor changes. Caspofungin (CAS) was chosen as the empirical treatment for patients without the above-mentioned pulmonary findings. Galactomannan assay could not be implemented for all patients due to the unavailability of the test in the laboratory.

Primary prophylaxis against invasive *Aspergillus* infections with posaconazole (POS) was considered for patients who were undergoing intensive chemotherapy for acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) in whom the risk of invasive aspergillosis without prophylaxis was substantial. Secondary antifungal prophylaxis with either POS or VOR was considered for patients who had proven or probable or possible fungal infection that responded to antifungal treatment under chemotherapy. Antifungal prophylaxis was administered to patients during the neutropenic phase and it was discontinued after recovery from neutropenia. Blood samples drawn from vein or catheter were inoculated into BactAlert 3D bottles (bioMérieux Diagnostics, Lyon, France). In addition, samples from urine, sputum, wound, conjunctive, abscess, blood and catheter were inoculated onto 5% sheep-blood agar (Salubris Inc., Istanbul, Turkey), or chocolate agar (Salubris Inc., Istanbul, Turkey) and MacConkey agar (Salubris Inc., Istanbul, Turkey). Isolated yeasts from blood cultures were identified by morphologic examination on Sabouraud Dextrose Agar (Unipath Ltd., Basingstoke, England) plates, germ-tube formation and API ID 32C (bioMérieux Diagnostics, Lyon, France) at the species level.

The ATB Fungus 2 microdilution kit was used (bioMérieux Diagnostics, Lyon, France) for susceptibility testing according to the CLSI (formerly NCCLS) broth microdilution M27-A2 protocol. Aspergillus galactomannan antigen test was performed using the Platelia commercial enzyme immunoassay kit (Platelia Aspergillus EIA; Bio-Rad Laboratories, Marnes-la-Coquette, France). Blood samples of patients were analyzed twice weekly and results were computed as an index which 0.5 and greater was considered as positive relative to optical density of the control sample measured with a semiautomatic analyzer (Behring ELISA processor III; Dade Behring, Marburg, Germany). Possible causes of false-positive and –negative results were eliminated. The test was considered significant if patient had two consecutive galactomannan assays with an index of 0.5 and greater under persistent or recurrent fever after 4–7 days of antibiotics with or without microbiologic or radiological findings associated with fungal infections as mentioned above and whose overall duration of neutropenia was expected to be more than 7 days.

Response to treatment was defined as defervescence in 48-72 hours subsequent to initiation
antifungal therapy, recovery of increased C reactive protein (CRP) level, leukocytosis or leukopenia, recovery of vital signs and clinical symptoms associated with infection (improvement in arterial blood-gas values, radiological improvement, negative urine culture for urinary system infection and recovery of signs and symptoms related to other infections). In-hospital mortality during the neutropenic phase and the clinical outcomes of febrile neutropenic episodes were the primary consequences that were investigated in this study.

Statistical analysis
Continuous variables were described as mean± standard deviation and range. Percentile values were described without decimals. Overall mortality associated with febrile neutropenia was defined as death within 30 days after development of neutropenia.

Results
We retrospectively analyzed 86 consecutive patients with neutropenia and their 148 febrile episodes. Of the 86 patients, 45 were male and the mean age was 47.65±15.06 years (range: 17–82 years). Mean MASCC score was 18.72 ± 9.43. Hematological malignancies of the patients are presented in Table 1.

Systemic antifungal drug was initiated to 17 patients with probable fungal infection and 12 patients with possible fungal infection. There was no proven infection associated with Zygomycetes or Fusarium species. Isolated fungal pathogens are presented in table 2.

BAL: Bronchoalveolar lavage, VOR: Voriconazole, AM-B: Liposomal Amphotericin B, CAS: Caspofungin
Voriconazole and fluconazole resistance were identified in each isolate of *Candida parapsilosis*, *Candida glabrata* and *Candida albicans* species. In total, five patients with acute myeloid leukemia and two patients with acute lymphocytic leukemia were treated with a combination of antifungal drugs due to persistent fever and negative culture and deterioration. Empirical antifungal therapy was initiated with AMB in seven patients, CAS in twelve patients and VOR in ten patients who had thorax CT findings compatible with pulmonary fungal infection. VOR and liposomal AM-B combination were used in two patients.

One of the patients responded to treatment, while the other could not tolerate treatment due to hallucinations, a known side effect of VOR. VOR and CAS combination were used in four patients empirically and none of them responded to treatment. Liposomal AM-B and CAS combination were used in two patients empirically, one of whom responded to treatment. POS prophylaxis was given to seven patients.

One patient with colostomy could not tolerate it due to diarrhea, and POS was modified to an intravenous antifungal drug in four patients due to persistent fever, new infiltration in thorax CT, and deterioration. Only two patients did not need antifungal treatment under induction chemotherapy, whereas five patients who experienced POS primary prophylaxis received systemic antifungal treatment due to possible fungal infection. POS maintained clinical and microbiologic responses that were achieved with either liposomal AM-B or CAS in the patients due to possible and probable fungal infections. Overall mortality rates were 26% (n:23) and 17 patients died due to infection. MRSA bacteremia (n:2), candidemia (n:5) and vancomycin sensitive *Enterococcus faecium* that induced severe sepsis (n:1) were recorded in patients who died.

**Discussion**

Our patients did not exhibit the expected benefits of primary prophylaxis with POS, although they were a small group. Studies related to POS prophylaxis versus fluconazole prophylaxis in the above-mentioned group of patients revealed a lower incidence of neutropenia in the patient group that received POS9,10. However, when probable cases are removed, the advantage in using POS disappears11. In the abstract that Gomes and colleagues presented at the European Congress of Clinical Microbiology and Infectious Diseases (ECCMID) in 2012, antifungal drugs including VOR (intravenous and oral), fluconazole, echinocandins (CAS, micafungin and anidulafungin) were compared for effectiveness in primary antifungal prophylaxis.

Invasive fungal infection developed in two of 24 patients who received oral POS and one of 24 patients who received oral fluconazole12. It should be noted that prophylaxis could lead to selection of resistant strains in patients and environmental flora. It is obvious that more studies focused on primary prophylaxis are needed and primary or secondary antifungal prophylaxis should be evaluated in terms of provided benefits and disadvantages13.

*Candida* species predominated confirmed fungal infections in our study. Colonization of the mucosal membranes by *Candida* species preceded invasive diseases, while *Aspergillus* and other molds invade the respiratory tract13.

VOR was modified to other antifungal drugs in patients who were infected with *Candida* species due to antifungal resistance. It should be taken into consideration that breakthrough with *Candida* infection can develop under VOR treatment due to azole resistance. This was previously shown in *Candida* species where either AMP-B or CAS should be given as an empirical antifungal drug in accordance with the recommendations of IDSA and MSG/IFICG/EORTC groups, if there is no evidence to support an *Aspergillus* infection (14,15).

**Conclusion**

It is obvious that more studies focused on primary prophylaxis are needed and primary or secondary antifungal prophylaxis should be evaluated in terms of provided benefits and disadvantages. Timely and appropriately initiated antifungal treatment is one of the most important factors for a good prognosis for recovery from a neutropenic phase.
