Background: Extensive approaches to the thoracic and lumbar spine are required for tumours, fractures, malignancies, deformity corrections and degenerative diseases. The body cavities (thorax and abdomen) require different approaches depending on the primary pathology and the desired exposure plus fixation method. There is usually two teams involved: the ‘exposure surgeon’ and the ‘operating surgeon’. Such a team is usually not feasible in developing countries. The purpose of this paper is to find out whether it is safe for a single surgeon to do both the exposure and the operation.

Methods: Nineteen patients operated on by a single surgeon over a three-year period were reviewed. This is a retrospective study. The information was obtained from clinical records.

Results: There were 10 females and 9 males, all below the age of 60 years. Four cases were due to infection, 14 due to trauma and 1 due to metastasis. The approach was dictated to by the pathology. The approaches were thoracotomy in 5, trans-thoracic trans-diaphragmatic retroperitoneal in 5 and 12th rib sub costal retroperitoneal in 9.
There were 4 intra-operative and 1 post-operative significant complications. All were managed successfully.

**Conclusion:** An experienced spinal surgeon can safely do both the approach and operative intervention. The complications can be safely managed. There is no increase in the complication rate.

**Introduction**

Extensive exposures to the thoraco-lumbar spine is indicated in trauma, infection, degenerative disease, tumours and deformities. The type of exposure depends on the location of the pathology and the extend of the accessibility required. The approach may be transthoracic (thoracotomy), transthoracic-transdiaphragmatic and retroperitoneal (TTTDRP) or sub diaphragmatic retroperitoneal (12th rib sub diaphragmatic RP). These are technically difficult and potentially dangerous approaches. The learning curve is also very steep.

In most developed countries, there is a team made up of ‘exposure surgeons’ and ‘operating surgeons’. The former will generally be either general or vascular surgeons and the latter will either be spinal orthopaedic or neurosurgeons. The ‘exposure surgeons’ are considered suitable for this surgery because of their unique knowledge of the area and the retroperitoneal structures.¹ There may also be a ‘dedicated team’ for such extensive operations.² The availability of such a team is rare in developing countries. The number of patients who need such an expertise or service is very large. The available surgeon must simply be so versatile as to act as both the ‘exposure’ and ‘operating’ surgeon if he is to be of value to the community. This is a huge undertaking for a single surgeon. The purpose of this paper is to find out whether there is an increase in the complication rate when a single surgeon does both the exposure and the surgery. The surgical techniques and the approaches described are not novel. The author does not specifically focus on the outcome of the operative procedures per se.

Materials and Methods

This retrospective study was undertaken at a secondary 800-beds hospital affiliated to the tertiary institution. Patients treated for thoraco-lumbar pathology from March 2006 up to June 2009 were all operated on by the author. The information was collected prospectively using a pro-forma. No IRB approval was needed for review of retrospective studies. The demographic data, primary pathology, surgical approach, type of operation and the complications are illustrated in the accompanying table.

Results

There were 19 patients with an average age of 37 years (range: 14 - 55 years).

There were 10 females and 9 males. The pathology was: trauma (n = 14), infection (n = 4) and metastasis (n = 1). The position during surgery was right lateral decubitus (in all) plus prone in those who needed additional transpedicular screw fixation. The approach was from the left side. Five patients needed thoracotomy (Figure 1), five TTTDRP and nine 12th rib subdiaphragmatic RP. All cases had corpectomy plus anterior instrumentation. Patients 9 and 15 needed additional posterior transpedicular screw fixation. The former had simultaneous anterior and posterior procedure and the latter had a staged operation (figure 2). The average duration for the operation was 3.0 hours (range: 2.5 - 3.5 hours) for anterior procedures. The patient who needed anterior plus posterior procedure during the same anaesthesia took 5.5 hours. The average blood loss was 600 milliliters (ml) (range 300 - 900ml). Patient 9 had the highest blood loss of 1500ml.
All patients were admitted to the high-care unit post-operatively. The average stay in high-care was about 4 days (range 3-5 days). There were no intra-operative or immediate post-operative mortality. No patient needed revision surgery either because of technical complications or implant problems.

Significant complications were recorded in all cases. These are complications that either needed corrective actions during the operation or the complications affected the course of the final event. There were five significant complications: four were intra-operative (2 pneumothoraces, one diaphragmatic and pleural tears and one fracture of the vertebra during internal fixation) and one post-operative (sepsis of bone-graft donor area). All were managed successful. The follow-up was, on average, 11 months (range 1 - 30 months).

Discussion

A single surgeon can safely do both the extensile exposure and operative intervention. The complication rate is fairly low and is not higher than those reported in the literature. The types of complications, though significant, were fairly easy to handle and did not affect the final outcome. It should always be borne in mind that both the exposure and the operation are technically very demanding and dangerous.

Very few spinal surgeons perform these spinal procedures independently. Holt Richard et al. reviewed 450 patients done by a single spinal surgeon for deformity corrections, fractures, tumours, infections and degenerative disease of the spine. They concluded that the complication rate is lower.

Thoraco-lumbar procedures have a high complication rate: may reach up to 31%. Major complications may be up to 11%. Antero-lateral approach via the left side has a very low complication because all major structures are under direct vision. Up to 50% of patients who had thoracotomy experience pulmonary complications. Anterior and posterior procedures (360° spinal operation) during the same anaesthesia carries a higher complication rate. A staged procedure in this case has a lower complication rate. Staged procedure is safe, has low blood loss and is reliable. The availability of two surgical team in such cases is an important factor in the success of the procedure. Such a team maximizes available surgical skills and therefore decreases the complication rate.

The limitations of the study are: retrospective in nature, few patients and there is no comparative group.

Conclusion

A well-trained and experienced spinal surgeon can safely do the approach and surgery of the thoraco-lumbar pathology. The complication rate is acceptable.
