ABSTRACT

BACKGROUND: Total thyroidectomy has become a routine surgical procedure. However, postoperative complications are not rare and can lead to voice disorders. AIM: To study voice quality after total thyroidectomy. SETTINGS AND DESIGN: Prospective study over a period of 5 years in 395 surgical patients undergoing total thyroidectomy.

MATERIALS AND METHODS: The voice quality of patients was based on systematic preoperative and postoperative laryngeal and voice examination. Voice assessment was performed by means of a voice quality questionnaire and recovery time within 12 months postoperatively. Patients who had inferior laryngeal nerve palsy were excluded from the study. RESULTS: Preoperative subjective voice disorders were found in 21% of patients, and 49% had voice impairment after surgery. The recovery time was less than 1 month for one-half of the patients with impaired voices, and 85% of the patients had recovered their voice after 5 months. At the 1-year postoperative examination, the permanent impaired voice rate was 1.26%. CONCLUSION: Voice impairment is common after thyroidectomy but usually transient, and less than 20% persist at 6 months. Patients must be informed about the risk of voice impairment after thyroid surgery. An objective voice assessment is desirable to monitor the presence and progress of voice disorders.

Key words: External laryngeal nerve palsy, inferior laryngeal nerve palsy, thyroid surgery, total thyroidectomy, voice disorders

This 5-year prospective study (1998-2002) investigated voice disorders related to thyroid surgery performed on a total of 395 surgical patients. It was designed to determine the frequency of subjective voice disorders after total thyroidectomy and to establish the recovery time and the frequency of persistent voice disorders after a 1-year follow-up.

Materials and Methods

Population

The study population consisted of 395 patients (320 females and 75 males) with a mean age of 55 years undergoing total thyroidectomy.

The overall rate of significant smokers (20 cigarettes per day) was 13% of cases. This low smoking rate compared to the general smoking rate of France (35%) can be explained by the fact that most patients were relatively elderly women.

As many as 11.65% of the patients in this study cohort were singers (46 patients).

Pathological findings

Multinodular goiter (340 patients): 88.5% (with laboratory signs of hyperthyroidism in 32% of cases and substernal development in 15% of cases)

• Graves’ disease (25 patients): 6.5%
• Thyroid cancer: 5% (20 patients with papillary cancer, 8 T1 and 12 T2)

Microscopic cancers associated with multinodular goiter less than 10 mm in diameter with no aggressive histological features (well-delimited capsular, no vascular embolus, no nodes) were grouped with multinodular goiter.

Method

The study inclusion criteria were as follows:

• Patients of all ages and either gender
• Thyroid diseases constituting an indication for total thyroidectomy
• No previous thyroid surgery
• No previous external-beam radiotherapy to the neck

• No postoperative recurrent laryngeal nerve palsy

The study was conducted according to the Evin’s Law, which concerns the ethical procedures in medical research in France. Patients were informed, and they consented to take part in this study.

This study was based on subjective assessment of voice quality before and after thyroid surgery by patients and their family, using a standard questionnaire.

A voice assessed as being usual by the patients and their family was considered to be a normal voice; conversely, an unusual or modified voice was considered to be abnormal.

In patients with voice disorders, the patterns of voice impairment were classified as follows:

Hoarseness: 62%
Voice fatigue: 21%
Pitching difficulty: 21%
Low voice: 13%
Weak voice: 5%

Postoperative voice assessment

All results are mentioned in Tables 2 and 3.

In the 87 patients who had an abnormal voice at the initial preoperative assessment, most of these abnormalities had resolved; except for 8 patients, who had an impaired voice at the 1-year follow-up assessment.

RESULTS

Preoperative voice assessment

As many as 87 out of the 395 patients reported having voice troubles before thyroid surgery. All details are mentioned in Table 1.

Postoperative voice assessment

At the 1-year postoperative assessment, only 5 out of 151 patients (3%) still had an impaired voice. Overall, 13 patients had persistent voice disorders at the 1-year follow-up assessment.

External laryngeal nerve palsy

No clear link was established between voice impairment and external laryngeal nerve injury as a result of stroboscopic laryngeal examination. In a series of 50 randomized total thyroidectomies, we tried to locate the external laryngeal nerve in the superior thyroid pedicle using a neurostimulator. Bilateral cricothyroid muscle contraction was observed in 20% of cases. Finally, two patients had persistent voice troubles which were attributed to external laryngeal nerve palsy, because the nerves were not clearly identified during surgery though laryngoscopic and stroboscopic postoperative examinations were considered normal.

Inferior laryngeal nerve palsy

During this period of study, 11 patients had inferior laryngeal nerve palsy (8 transient and 3 definitive). These patients were excluded from this study because their voice troubles were real and not actually subjective because of the inferior laryngeal nerve palsy. It concerned 11 women who underwent total thyroidectomy for benign multinodular goiter.

Indian J Med Sci, Vol. 61, No. 8, August 2007
Persistent voice troubles after 1-year follow-up
At the 1-year examination, communication difficulties due to voice impairment were assessed by another questionnaire. Among the 13 patients with persistent voice disorders, 12 had pitching difficulty when calling, 10 when phoning, 8 in a noisy environment, 6 mainly had difficulties at work and 5 even had difficulties at home. The singing voice was modified in 27 cases of the group of 46 ‘singers.’

Statistical analysis
Descriptive statistical analysis was performed before univariate tests. Chi-square or Fisher’s exact tests were used to analyze nominal data. Quantitative differences between groups were analyzed by ANOVA or a Student ‘t’ test. The correlation between scale data was performed by a correlation test. P values less than 0.05 were considered to be statistically significant.

DISCUSSION
The strengths of the present study are multiple – no patients lost of view, a quite large number of patients authorizing coherent statistical analysis and the prospective procedure. The principal limitation of the study is the lack of objective data concerning laryngeal function. However, this study makes a twofold contribution:

• The patterns of voice disorders are described with the same preoperative and postoperative questionnaire.
• A 1-year follow-up of the recovery of each voice disorder was performed.

Preoperative voice impairment
Preoperative voice impairment, frequent in this study (20%), must be recognized, recorded and correlated with the laryngeal examination (vocal fold mobility, mucosal abnormalities, stroboscopy).[7-10] Preoperative (and postoperative) voice disorders may modify conversation or pitching or the singing voice. Physicians should inform patients that transient voice disorders (and also swallowing symptoms) may occur following total thyroidectomy.[8] The origin of preoperative voice impairment can be multiple. A thyroid origin of recurrent laryngeal nerve palsy is rare before surgery and is usually related to thyroid cancer. Preoperative dysphonia may correspond to pharyngeal voice, secondary to modifications of the resonators caused by a bulky cervical goiter. In this case, a cervicothoracic CT scan is recommended to detect possible retropharyngeal extension of the goiter. Graves’ disease and hyperthyroidism may also cause dysphonia, though it was not significant in this study. Most cases of preoperative voice impairment are observed in a context of normal thyroid hormone levels. In these cases, postoperative recovery cannot be predicted, although one-half of these patients recover. Finally, in this study, only 9% of patients with preoperative voice impairment still had voice impairment, 1 year after surgery, which suggests that thyroid diseases may be directly involved in preoperative voice disorders and usually recover (91% of cases) after surgery.

Postoperative voice impairment
In this study, after surgery the voice deteriorated in nearly one-half of patients, and most patients presented several pathological patterns. The average recovery time was 2 months and was not significantly different according to voice patterns. Nearly one-half of patients with voice disorders recovered within the first month. Finally, five patients with normal preoperative voice had persistent voice disorders after 1-year of follow-up.

Subjective or objective voice disorders are rarely described in the medical literature.[14] Yeung found that preoperative voice and laryngeal examination is significant and reported dysphonia in 9% of cases, with 22% of laryngoscopic abnormalities, 4% of decreased vocal fold mobility and just one case of recurrent laryngeal nerve palsy.[15] Keilmann reported 43% of postoperative voice disorders: 12% of cases persisted 1 year after surgery (without any recurrent laryngeal nerve palsy); dysphonia occurred in 25% of cases after total thyroidectomy, 11% after unilateral lobectomy and only 5% of cases when the external laryngeal nerve was identified and preserved. This study suggests that external laryngeal nerve injury is involved in the pathogenesis of voice disorders with mobile larynx after thyroid surgery. The risk of voice disorders is also higher after total thyroidectomy than after unilateral lobectomy.[17] Mac Ivor studied voice before and after 50 thyroid surgical procedures. Voice was worsened in 22.7% of cases and improved in 18% of cases. Subjective voice disorders were correlated with objective signs in 65% of cases.[19] Hong performed voice assessment after 54 surgical procedures. Subjective voice disorders consisted of voice fatigue, pitching difficulty and worsening of the singing voice, and objective voice changes were a lower frequency without modification of the fundamental frequency of maximum phonation time.[13] Debruyne performed preoperative and postoperative recording of objective voice parameters. On the fourth postoperative day, he found a 12-Hertz decrease of the speaking fundamental frequency, a semitone decrease of voice pitch and harmonics. All these changes had resolved at the 2-week postoperative checkup except for decreased speaking fundamental frequency.[12]

Causes of postoperative voice impairment
The causes of voice disorders without recurrent laryngeal nerve palsy are probably multiple, including external laryngeal nerve injury; cricothyroid muscle injury; large laryngotracheal skeleton dissection, especially when the infrahyoid muscles are sectioned; and orotracheal intubation. Like Hong, we believe that large dissection is responsible for the majority of rapidly recovering postoperative voice disorders.[11] The surgical approach should be as minimal as possible, especially using small cervical incision and respecting the infrahyoid muscles, which should be sectioned only if necessary (huge goiters, thyroid cancer...)

with extraglandular extension).

Moreover, the frequent postoperative body positions – head bent, shoulders forward and larynx lowered – can lead to a lower voice speaking frequency and pitching difficulties.

The cause of more persistent voice disorders, with or without hoarseness, may be external laryngeal nerve injury, cricothyroid muscle injury or possibly transient ‘functional’ external laryngeal nerve impairment, just like transient recurrent laryngeal nerve palsy. We hypothesize that surgical procedures with systematic dissection of the recurrent laryngeal nerve may increase the frequency of postoperative dysphonia without recurrent laryngeal nerve palsy. Conversely, surgical procedures without recurrent laryngeal nerve dissection may decrease the frequency of the postoperative dysphonia but increase the rate of permanent recurrent laryngeal nerve palsy. In our experience, the rate of detecting the external laryngeal nerve using a neurostimulator is about 20%. It is explained by the fact that we do not aim to dissect it. Ultrasound images of superior thyroid artery and veins close to the gland, no coagulation (eventually only small selective controlled bipolar coagulation can be performed) in the cricothyroid space and on the cricothyroid muscle are sufficient to respect the external laryngeal nerve.

Thyroid surgery and voice management

Laryngeal examination must be performed before thyroid surgery and must comprise at least preoperative and postoperative laryngoscopy and follow-up for a period of 6 months to 1 year after surgery in patients with postoperative voice disorders.[16] Williams did not consider routine stroboscopy to be useful.[16] A voice questionnaire can also be systematically proposed before and after surgery [Table 4].[13]

Postoperative voice disorders without recurrent laryngeal nerve palsy are considered to be permanent when they persist for 6 months[15] or 12 months[16] after surgery.

CONCLUSION

Voice disorders after total thyroidectomy are relatively frequent and present in various ways. They can be functional and transient or, sometimes, permanent.

Preoperative and postoperative voice assessment must be performed systematically. Patients must be informed about the frequency of postoperative voice disorders, which are usually transient. An objective voice recording should be performed when preoperative or postoperative dysphonia is observed to allow correlation with subjective voice impairment patterns.
