Subperiosteal hematoma of the orbit associated with subfrontal hematoma presenting as proptosis

Sir,

Blunt trauma to the head may result in extradural hematomas, which are common over the temporoparietal region and associated with injury to the meningeal arteries. Subperiosteal hematomas of the orbit are rare presentations after head injury, with only a few cases reported in the literature.[1,2] We report a rare case where extradural orbital hematoma presented as proptosis following head injury in a conscious young boy. A 14-year-old boy from rural central India presented with history of fall from the bicycle one day ago. He sustained injury in the form of a scalp contusion over the left frontal region. There was no history of loss of consciousness or any bleed from the oral, nasal or auricular orifices. He had no signs of raised intracranial tension or any neurodeficits. The patient was admitted for observation. Next day he developed proptosis of the left eye, which gradually progressed over 24h. He also developed throbbing pain over the left orbit and complained of diminution of vision by Day 2. On examination he was fully conscious, with a normal Glasgow coma scale. Bilateral pupils were equal and normally reacting to light. He had restriction of movements of the left eye, with marked limitation of elevation and slight limitation of depression, abduction and adduction. Fundus revealed a hyperemic disc, macular edema, absence of spontaneous venous pulsations and slightly dilated and tortuous retinal veins. He had no cranial nerve palsy or long tract signs. Proptosis of the left eye was observed. X-ray skull revealed no bony abnormality. Computed tomography (CT) of the head demonstrated a large frontal and subfrontal extradural hematoma, which was pushing the left eyeball anteriorly [Figures 1, 2]. No orbital roof fracture was demonstrated. He underwent left frontal craniotomy, superolateral orbitotomy and both hematomas were evacuated. Proptosis resolved immediately after evacuation. Visual acuity returned to normal on the second postoperative day. Postoperative course was uneventful. After four months of follow-up, patient was asymptomatic and attending school. The present case reported is rare, as only a few cases of retro-orbital subperiosteal hematomas have been reported previously. All the previous case reports, including the present one have been in young males. This is likely due to higher incidence of trauma in them and also because orbital periosteum is easily detachable.[1,2] Apart from trauma other rare causes of retro-orbital subperiosteal hematoma include giant cephalhematoma,[3] sickle cell disease[4] and chronic sinusitis.[5] As the proptotic eye is pushed anteriorly against the canthus, pressure within the eye increases until there is inadequate perfusion of the eye due to the pressure effects. This can lead to diminution in vision as in our case. Preservation of consciousness is also rare in previous reported cases. In a series of 10 cases of extradural hematomas with proptosis reported previously,[1] eight had impaired consciousness and associated frontal hematoma. The present case did not have any orbital roof fracture. In a previously reported case series retro-orbital hemorrhage was reported in only two cases and one of them had fracture of the orbital roof.[1] It is important to recognize and treat this condition early, as extradural hematomas have a high mortality.[1,2] Computed tomography scan of the orbit is the most common method of diagnosing a retrobulbar hematoma. Bedside CT scan, in a busy emergency setting ultrasonography may aid in the rapid diagnosis of a retrobulbar hematoma.[5] This case also signifies the importance of prompt surgical intervention, as the patient had a complete recovery.

Ganglion: An uncommon cause of compressive peroneal neuropathy

Sir,

Peroneal nerve injury usually results from fracture of the fibula neck or direct pressure from an ill-fitting plaster cast.[1] Ganglionic cysts developing in the sheath of the peroneal nerve or joint capsule around the knee is a rare cause of compressive peroneal neuropathy.[1-3] We report a rare case of compression of peroneal nerve by ganglion and discuss the clinical and radiological features. A 40–year-old female presented with slowly progressive swelling in the upper lateral aspect of the left leg since one year. It was associated with progressive weakness of the left great toe with loss of sensation over it. There was no history of trauma or any other swellings. Her general and systemic examination was unremarkable. Neurologically she had weakness of left EHL (Extensor hallucis longus) of Grade 3/5 with loss of sensation in S1 dermatome. Local examination revealed a 10X3cm in size, ill-defined, firm, non-tender, non-pulsatile, immobile swelling on the lateral aspect of the upper part of the left leg Figure 1. The skin over it was free and healthy. Blood investigations were normal. The MRI of the left leg and knee showed hypointense lesion on T1W images, extending from the proximal tibiofibular joint region and displacing...
