Giant extra-axial posterior fossa tuberculoma in a three-year-old child

Sir,

Intracranial tuberculosis, meningitis, and parenchymal tuberculomas, are still prevalent in some parts of the developing world. Of the intracranial tuberculomas, extra-axial tuberculomas are rare and may present with diagnostic dilemmas.[1]

A three-year-old girl presented with progressive enlargement of head, difficulty in walking and sitting, and progressive stiffness of all the four limbs since one year. There was no history of headache, vomiting, or fever. Developmental history suggested delay in acquiring milestones. On examination, there was macrocephaly, bulging anterior fontanelle, up gaze palsy, and increased tone in all the four limbs. Routine blood tests and chest X-ray were normal. Contrast computed tomography (CT) brain showed [Figure 1] a large ring enhancing (51 × 51 × 60 mm) lesion in the left posterior fossa compressing and shifting the fourth ventricle to right side causing obstructive hydrocephalous. There was extension of the lesion to supratentorial compartment through tentorial hiatus. A right ventriculoperitoneal shunt was done followed by definitive surgery. Midline suboccipital craniectomy and durotomy was done. At operation there was a large extra-axial lesion attached to tentorium superiorly and to brainstem medially compressing the cerebellum laterally. There was extension of the lesion to supratentorial compartment through tentorial hiatus. The tumor was yellowish, firm, and relatively avascular. Total excision of the lesion was done [Figure 2]. Histopathology was tuberculoma [Figure 3]. The patient improved postoperatively and was discharged on antituberculous treatment. At one-year follow up the patient is asymptomatic.

In developing countries, tuberculomas still account for about one-third of brain masses.[2] Of the intracranial tuberculomas, extra-axial tuberculomas are extremely uncommon.[1,3] Tuberculoma usually results from the hematogenous seeding of the tubercle bacilli to the leptomeninges and brain parenchyma, resulting in the formation of tubercles. The leptomeningeal tubercles
may rupture into the subarachnoid space resulting in meningitis or may remain confined to the meninges forming a hard fibrous mass attached to the dura which may present as tuberculoma-en-plaque,\textsuperscript{[4,5]} or extra-axial mass like meningioma.\textsuperscript{[3,6]}

Extra-axial tuberculomas can present with the clinical picture like any other mass lesion, hence, preoperative differential diagnosis from other mass lesions is difficult. The differential diagnosis includes meningioma,
lymphoma, metastatic tumor, and sarcoidosis. Findings of systemic infection and many of the usual laboratory correlates of infection may be absent. Cerebrospinal fluid examination may not be informative.

CT and magnetic resonance (MR) imaging features are highly sensitive for tuberculoma, but their specificity for a definite diagnosis is low. Tuberculoma may be seen as a hypo or hyperdense, round or multilobar lesion on CT, and shows homogeneous or ring enhancement. The MRI signal characteristics of intracranial tuberculoma are extremely diverse. An isointense or hypointense core with a hyperintense rim on T2-weighted and FLAIR images is the most common presentation. Core hypointensity of lesion is related to necrosis and the large number of cells. MR spectroscopy may be complementary in the diagnosis and show elevated lipid peak, cholesterol ester, plasmalogen, and phenolic glycolipids. This finding may also help to differentiate tuberculomas from other disease conditions such as malignant tumors as well as the common extra-axial tumor like meningoias. Large lesion with mass effect was the indication for surgery in this patient. Surgical excision not only helped to establish the histological diagnosis but also helped to resolve the compressive symptoms.
