THE COCAINE ‘BODY-PACKER’ SYNDROME: DIAGNOSIS AND TREATMENT

Sir, A 56-year-old African man was found unconscious at Al Doha airport in the state of Qatar at 11:00 am. The patient was unconscious, tachypnic, pupils were fixed and dilated, blood pressure 150/90mmHg, Pulse 105/min, and the oral temperature was 37.0°C. Because the individual was alone and unresponsive no past medical history was obtained. The patient was taken from the airport to the accident and emergency (A&E) department. Upon arrival to the A&E department he developed generalized seizures. On examination, the patient was unconscious, tachypnic, afebrile, pupils were fixed and dilated, blood pressure 150/90mmHg, Pulse 105/min and the oral temperature was 37.0°C. Arterial blood gas analysis at room air showed pH = 7.468, pO2 = 65 mm Hg, pCO2 = 30 mm Hg, HCO3 24 mmol/L.

The haemoglobin, platelets, leucocyte count, blood sugar, serum electrolytes, and serum creatinine, were within normal range. Liver function test and coagulation profile were normal, as well as brain computed tomography scans. The remainder of the examination was unremarkable. He was intubated and admitted to medical intensive care unit.

Plain abdomen X-ray showed two packets in the stomach [Figure 1a] and one packet in the rectum [Figure 1b]. The packets were removed by an endoscopy. [Figure 2a] showed one of the removed packets from the stomach. [Figure 2b] the packet removed from the rectum. Each packet weight approximately 80 grams.

After removing the packets, the patient was treated conservatively, he regained his consciousness after five days. Analysis of the materials in the packets revealed cocaine which was also detected in the urine. The patient was seen by a psychiatrist and later on he was taken to the prison.

Body packers are people who illegally carry drugs, mostly cocaine and heroin, concealed within their bodies. The packets can be made of various materials, but most often are condoms, which are easily available on the market. The packets are inserted in the mouth, rectum or vagina in order to get across borders without being detected. After the body packer swallows these packets, constipating agents, such as diphenoxylate or loperamide, are frequently used.[1] Transit times may be as brief as one or two days or as long as two to three weeks. After entering the country of destination, body packers use laxatives, cathartics, or enemas to help pass their cargo rectally.[2]

Body packers usually present to health care providers for one of three reasons,[3]: drug-induced toxic effects, intestinal obstruction, or medical assessment after detention or arrest. This patient developed life threatening cocaine toxicity from leakage of the contents of these packages into his bowels.

A detailed history should be obtained. However, body packers are often dishonest historians. In rare cases, like in this case, patients may be unable to provide a history owing to profound drug-induced toxic effects. Body packing should be suspected in anyone with signs of drug-induced toxic effects after a recent arrival on an international flight or when there is no history of recreational drug use.

Cocaine toxicity causes anxiety, dilated pupils, diaphoresis, tachycardia, and hypertension, followed by hyperthermia, seizures, and cardiovascular collapse. Patients suspected of being body packers require radiographic evaluation.

Patients who are asymptomatic can be treated conservatively and expectantly until the packets pass. Whole bowel irrigation (WBI) should be started with a polyethylene glycol/electrolyte lavage solution.[4,5]

Although endoscopic removal of packets is acceptable, it has generally become accepted that cocaine body packers who show signs of cocaine toxicity or gastrointestinal obstruction should undergo immediate emergency surgery.

AN ELDERLY MAN WITH DYSPHAGIA AND DYSARTHRIA

Sir, An 81-year-old man was admitted to hospital with a 2-day history of slurred speech and swallowing difficulty. There was no history of weakness in the limbs, diplopia or difficulty in breathing. He had enjoyed good health up until...
this event and his only medical problem was hypertension. He was taking losartan 50 mg, bendrofluazide 2.5 mg and aspirin 75 mg. He was a smoker and consumed little alcohol occasionally.

He was well built, alert and oriented. He had good strength in all limbs and there was no focal weakness, reflexes were normal with downgoing plantars. There were no cerebellar signs. However, he was dysarthric and also had difficulty swallowing. The blood pressure on admission was 220/100 mm Hg. Full blood count, inflammatory markers and biochemical profile were within the normal range. Electrocardiogram and chest x-ray were normal. Computed tomography (CT) scan of brain showed moderate generalised cerebral and cerebellar atrophy. With the background of hypertension and smoking in an elderly man a diagnosis of stroke was made, and the patient was transferred to stroke ward for rehabilitation. Assessment by speech and language therapist revealed reduced tongue movements with severe dysarthria, and poor swallow with no laryngeal elevation during swallow. Due to poor swallow and high risk of aspiration a Nasogastric (NG) tube was inserted for feeding. On the third day from admission the patient became short of breath and was unable to get out of bed. A diagnosis of myasthenia gravis was made, the patient was resuscitated and pyridostigmine was administered via the NG tube. The patient showed dramatic response to pyridostigmine and was then transferred to high dependency unit for further management. His acetylcholine receptor antibodies were elevated at 388.7 units (< 4.0). With the diagnosis of myasthenia gravis he was commenced on pyridostigmine 60 mgs six times a day along with prednisolone 60 mg daily. He had a normal CT scan of thorax and remains well at 8 months follow-up.

Myasthenia Gravis (MG) is a potentially serious but treatable disorder of neuromuscular transmission associated with acetylcholine receptor antibodies. The hallmark of the disease is fatigable weakness, however, the spectrum can range from mild ocular symptoms to severe generalised form and respiratory failure. Due to vague symptoms and associated co-morbidities diagnosis of MG in the elderly can be difficult and MG can mimic stroke in elderly patients. Kleiner-Fisman et al have described their experience of dysphagia and dysarthria in elderly patients with MG. Presentation with dysphagia and dysarthria as in our patient is not a common feature of MG. Our case demonstrates that MG can be misdiagnosed as stroke in the elderly, and delay in the diagnosis can be life-threatening. MG is substantially underdiagnosed in older people and should be considered as a diagnostic possibility in elderly patients with neurological features. Early and correct diagnosis may prevent complications from this treatable disease.
