*The diagnosis of human cutaneous leishmaniasis in small towns is sometimes made without the species identification of the Leishmania, even in areas without previous epidemiological surveys. Here we report the isolation of a Leishmania strain from a patient of Rincão, state of São Paulo, that was identified by isoenzyme characterization as L. (Viannia) braziliensis. Sand fly collections were made in the area where the patient live in order to investigate the likely vector species.*

Key words: *Leishmania braziliensis* - isolation - Brazil

Leishmaniasis is a zoonotic infection affecting 12 million people worldwide in 88 countries. The annual incidence is 2 million, with 1.5 million presenting the cutaneous form and 0.5 million the visceral form. In Brazil, American cutaneous leishmaniasis (ACL) is a widespread disease (Marzochi & Marzochi 1994). Since the beginning of the last century to nowadays, changes on the environment of the state of São Paulo have altered the epidemiological pattern of ACL from an epidemic to an endemic one (Tolezano 1994). Contrary to some predictions, that deforestation would lead to eradication of the disease (Marcondes 1996) re-described both species, adopting the genus *Nyssomyia* instead of *Lutzomyia* according to Galati (1995). Previous sand fly surveys carried out in Paulista Plateau showed that *L. intermedia* is strongly associated with gallery forest located at the edges of the rivers (Gomes et al. 1989). Further clinical and epidemiological studies are neces-
Isolation of L. (V.) braziliensis • MC Pinto et al.

It is necessary to evaluate incidence in the human population and the presence of *Leishmania* in wild and domestic animals and the vectors present in the present study area.
